Cranbury, NJ 08512

A novel highly stable hydrogen terminated silicon coating was synthesized by microwave plasma reaction of mixture of silane, hydrogen, and helium wherein it is proposed that He^+ served as a catalyst with atomic hydrogen to form highly stable silicon hydrides. Novel silicon hydride was identified by time of flight secondary ion mass spectroscopy and X-ray photoelectron spectroscopy. The time of flight secondary ion mass spectroscopy (ToF-SIMS) identified the coatings as hydride by the large SiH^+ peak in the positive spectrum and the dominant H^- in the negative spectrum. Since hydrogen is the only element with no primary element peaks, X-ray photoelectron spectroscopy (XPS) identified the H content of the SiH coatings as comprising novel silicon hydrides due to new peaks at 11, 43, and 55 eV in the absence of corresponding peaks of any candidate element at higher binding energies. The silicon hydride surface was remarkably stable to air as shown by XPS. The highly stable amorphous silicon hydride coating may advance the production of integrated circuits and microdevices by resisting the oxygen passivation of the surface and possibly altering the dielectric constant and band gap to increase device performance.

I. INTRODUCTION

Aqueous HF acid etching of silicon surfaces results in the removal of the surface oxide and produces hydrogen terminated silicon surfaces, $Si-H$. HF etching is a key step in producing silicon surfaces which are contamination-free and chemically stable for subsequent processing in the semiconductor industry [1-3]. In fact, chemical oxidation and subsequent HF treatment of Si surfaces are used prior to gate oxidation, where surface contamination (<10 ppm level) and interface control are crucial to device performance. Fluorine termination was initially considered the basis of the chemical stability of HF -treated surfaces. Subsequently, it was found that fluorine is a minor species on the surface and that the remarkable surface passivation achieved by HF is explained by H termination of silicon dangling bonds protecting the surface from chemical attack [3, 4, 5]. However, the replacement of the oxide layer with the H termination of the silicon dangling bonds by HF can be attributed to the increased electronegativity of fluoride ion versus oxide causing an enhanced reactivity of H^+ which attacks the oxide layer. The electron affinity of halogens increases from the bottom of the Group VII elements to the top. Hydride ion may be considered a halide since it possess the same electronic structure. And, according to the binding energy trend, it should have a high binding energy. However, the binding energy is only 0.75 eV which is much lower than the 3.4 eV binding energy of a fluoride ion. And, once the HF is rinsed from the surface, the $Si-H$ layer undergoes rapid oxidation when exposed to oxygen or solvents containing oxygen. An $Si-H$ layer with enhanced stability would be of great value to the semiconductor industry.

Amorphous $Si-H$ films, the active component of important semiconductor devices such as photovoltaics, optoelectronics, liquid crystal displays, and field-effect transistors are formed by plasma enhanced chemical vapor deposition (PECVD) techniques [6]. Typically the film is grown on a silicon wafer substrate exposed to a plasma of silane, hydrogen, and often argon using a reactor with a diode configuration in which the plasma is confined between two parallel electrodes. In this study, we find that the aqueous HF acid etched surface undergoes rapid oxidation when exposed to air and provides little protection from such exposure. Whereas, a novel highly air stable amorphous silicon hydride surface coating designated $\alpha-SiH$ was synthesized by microwave plasma reaction of mixture of silane, hydrogen, and helium wherein it is proposed that He^+ served as a catalyst with atomic hydrogen. The novel $\alpha-SiH$ film may advance semiconductor fabrication and devices.

It was reported previously that a new plasma source has been developed that operates by incandescently heating a hydrogen dissociator to provide atomic hydrogen and heats a catalyst such that it becomes gaseous and reacts with the atomic hydrogen to produce a plasma called a resonance transfer or rt-plasma. It was extraordinary, that intense VUV emission was observed [7] at low temperatures (e.g. $\approx 10^3 K$) and an extraordinary low field strength of about 1-2 V/cm from atomic hydrogen and certain atomized elements or certain gaseous ions which singly or multiply ionize at integer multiples of the potential energy of atomic hydrogen, $27.2 eV$. In this study, He^+ was used as a catalyst to form $\alpha-SiH$ since the second ionization energy of helium is $54.417 eV$, which is equivalent to $2 \cdot 27.2 eV$. In this case, $54.417 eV$ is transferred nonradiatively from atomic hydrogen to He^+ which is resonantly ionized. The catalysis reaction products are highly stable intermediates which react to form novel stable

hydrides. Hydride ions with high binding energies have been observed by XPS and by solid state magic-angle spinning proton nuclear magnetic resonance (^1H MAS NMR) having upfield shifted peaks [11-18]. Additional prior related studies that support the possibility of a novel reaction of atomic hydrogen which produces a chemically generated or assisted plasma (rt-plasma) and produces novel hydride compounds include extreme ultraviolet (EUV) spectroscopy [7, 9, 19-31], characteristic emission from catalysis and the hydride ion products [8-11, 22-24], emission of hydrogen intermediates [19-21, 27], plasma formation [7-10, 22-26, 32-33], Balmer α line broadening [10, 20, 27-28, 34], elevated electron temperature [20, 27-28], anomalous plasma afterglow duration [32-33], power generation [18, 27, 29-30, 34-35], and analysis of chemical compounds [11-18, 36]. The theory has been given previously [11-18, 36].

Even a partial coating of an extremely stable silicon hydride may stabilize a silicon surface to unprecedented time scales to increase the yield in integrated chip fabrication. In this paper, we report the results of the reaction of silane in a helium-hydrogen microwave discharge plasma at the surface of a nickel foil. After the plasma reaction processing, the surface was characterized by ToF-SIMS and XPS.

II. EXPERIMENTAL

Synthesis

Amorphous silicon hydride (α - SiH) films were grown on nickel substrates by their exposure to a low pressure microwave discharge of SiH_4 (2.5%)/ He (96.6%)/ H_2 (0.9%). The experimental set up comprising a microwave discharge cell operated under flow conditions is shown in Figure 1. The SiH_4 gas was introduced into a 1000 ml

reservoir by a gas/vacuum line where it was mixed with premixed He (99%)/ H_2 (1%) to obtain the reaction mixture SiH_4 (2.5%)/ He (96.6%)/ H_2 (0.9%) by controlling the individual gas pressures. Nickel foil (5 X 5 mm and 0.05 mm thick, Alfa Aesar 99+%) substrates were used to avoid charging during ToF-SIMS and XPS characterization. The substrates were placed inside of a quartz tube (1.3 cm in diameter by 15.5 cm long) with vacuum valves at both ends. The tube was fitted with an Opthos coaxial microwave cavity (Evenson cavity) and connected to the gas/vacuum line. The quartz tube and vacuum line were evacuated sufficiently to remove any trace moisture or oxygen. The gas mixture SiH_4 (2.5%)/ He (96.6%)/ H_2 (0.9%) was flowed through the quartz tube at a total pressure of 0.7 Torr maintained with a gas flow rate of 40 sccm controlled by a mass flow controller with a readout. The cell pressure was monitored by an absolute pressure gauge. The microwave generator shown in Figure 1 was an Opthos model MPG-4M generator (Frequency: 2450 MHz). The microwave plasma was maintained with a 40 W (forward)/15 W (reflected) power for about 20 min. Yellow-orange coatings formed on the substrates and the wall of the quartz tube. The quartz tube was removed and transferred to a drybox with the samples inside by closing the vacuum valves at both ends and detaching the tube from the vacuum/gas line. The coated substrates were mounted on XPS and ToF-SIMS sample holders under an argon atmosphere in order to prepare samples for the corresponding analyses. One set of samples was analyzed with air exposure limited to 10 minutes and another for 20 minutes while transferring and mounting during the analyses. Separate samples were removed from the drybox and stored in air at room temperature for 48 hours or 10 days before the analyses. Controls comprised a commercial silicon wafer (Alfa Aesar 99.99%) untreated, and HF cleaned silicon wafers exposed to air for 10 minutes or 3 hours.

ToF-SIMS Characterization

The commercial silicon wafer, *HF* cleaned silicon wafer, and α -*SiH* coated nickel foil samples were characterized using Physical Electronics TRIFT ToF-SIMS instrument. The primary ion source was a pulsed $^{69}\text{Ga}^+$ liquid metal source operated at 15 keV [37-38]. The secondary ions were exacted by a ± 3 keV (according to the mode) voltage. Three electrostatic analyzers (Triple-Focusing-Time-of-Flight) deflect them in order to compensate for the initial energy dispersion of ions of the same mass. The 400 pA dc current was pulsed at a 5 kHz repetition rate with a 7 ns pulse width. The analyzed area was $60\mu\text{m} \times 60\mu\text{m}$ and the mass range was 0-1000 AMU. The total ion dose was $7 \times 10^{11} \text{ ions}/\text{cm}^2$, ensuring static conditions. Charge compensation was performed with a pulsed electron gun operated at 20 eV electron energy. In order to remove surface contaminants and expose a fresh surface for analysis, the samples were sputter-cleaned for 30 s using a $80\mu\text{m} \times 80\mu\text{m}$ raster, with 600 pA current, resulting in a total ion dose of $10^{15} \text{ ions}/\text{cm}^2$. Three different regions on each sample of $60\mu\text{m} \times 60\mu\text{m}$ were analyzed. The positive and negative SIMS spectra were acquired. Representative post sputtering data is reported. The ToF-SIMS data were treated using ‘cadence’ software (Physical Electronics), which calculates the mass calibration from well-defined reference peaks.

XPS Characterization

A series of XPS analyses were made on the samples using a Scienta 300 XPS Spectrometer. The fixed analyzer transmission mode and the sweep acquisition mode

were used. The angle was 15° . The step energy in the survey scan was 0.5 eV , and the step energy in the high resolution scan was 0.15 eV . In the survey scan, the time per step was 0.4 seconds, and the number of sweeps was 4. In the high resolution scan, the time per step was 0.3 seconds, and the number of sweeps was 30. $C\ 1s$ at 284.5 eV was used as the internal standard.

III. RESULTS AND DISCUSSION

ToF-SIMS

The positive ToF-SIMS spectra ($m/e = 0 - 100$) of the noncoated cleaned commercial silicon wafer and a nickel foil coated with an $\alpha - SiH$ film and exposed to air for 10 min. are shown in Figures 2 and 3, respectively. The positive ion spectrum of the control was dominated by Si^+ , oxides $Si_xO_y^+$, and hydroxides $Si_x(OH)_y^+$; whereas, that of the $\alpha - SiH$ sample contained essentially no oxide or hydroxide peaks. Rather, it was dominated by Si^+ and a peak at $m/z = 29$ which comprised a contribution from SiH^+ and $^{29}Si^+$ which were difficult to separate definitively. However, the contribution due to SiH^+ could be determined by calculating the ratio $R = \frac{^{28}Si}{^{28}SiH + ^{29}Si}$. For comparison, the theoretical ratio of $\frac{^{28}Si}{^{29}Si}$ based on isotopic abundance is 19.6. R for the clean noncoated silicon wafer was 8.1. Whereas, R for the $\alpha - SiH$ sample was 1.15 indicating that the $m/z = 29$ peak was overwhelmingly due to SiH^+ .

The positive spectrum ($m/e = 0 - 100$) of a nickel foil coated with an $\alpha - SiH$ film and exposed to air for 10 days before the ToF-SIMS analysis is shown in Figure 4.

In this case R was 1.75 demonstrating that the sample was extraordinarily stable to air exposure. In contrast, R was 2.45 in the positive spectrum ($m/e = 0 - 100$) of the HF cleaned silicon wafer exposed to air for only 10 min. before ToF-SIMS analysis as shown in Figure 5.

The negative ion spectra ($m/e = 0 - 100$) of the noncoated cleaned commercial silicon wafer and a nickel foil coated with an $\alpha - SiH$ film and exposed to air for 10 min. before ToF-SIMS analysis are shown in Figures 6 and 7, respectively. The control spectrum was dominated by oxide (O^- $m/z = 16$) and hydroxide (OH^- $m/z = 17$); whereas, spectrum of the $\alpha - SiH$ film was dominated by hydride ion (H^- $m/z = 1$). Very little oxide or hydroxide was observed.

The negative spectrum ($m/e = 0 - 100$) of a nickel foil coated with an $\alpha - SiH$ film and exposed to air for 10 days before the ToF-SIMS analysis is shown in Figure 8. In this case, hydride ion also dominated the negative spectrum demonstrating extraordinary air stability of the $\alpha - SiH$ film. The negative spectrum ($m/e = 0 - 100$) of the HF cleaned silicon wafer exposed to air for only 10 min. before ToF-SIMS analysis shown in Figure 9 also shows a dominant hydride as well as oxide, hydroxide, and some fluoride (F^- $m/z = 19$). However, the HF treated surface was not stable with prolonged air exposure. A dominant oxide peak was observed in the negative spectrum ($m/e = 0 - 100$) of the HF cleaned silicon wafer exposed to air for only 3 hours before ToF-SIMS analysis as shown in Figure 10. Hydride was also observed in lesser amounts and may have resulted as a fragment of the observed hydroxide. Fluoride (F^- $m/z = 19$) was also observed. The ToF-SIMS results from the HF treated surface is consistent with

predominantly H termination of silicon dangling bonds as reported previously [3, 4, 5] that has undergone rapid oxidation to form mixed oxides such as $SiOH$.

These results indicate that the plasma reaction formed a highly stable hydrogenated silicon coating in the absence of fluorine observed on the HF treated surface. Remarkably, the $\alpha - SiH$ film was stable even after 10 days; whereas, the HF treated surface showed signs of oxidation over a 1500 times shorter time scale—10 mins. At 3 hours the HF treated surface had similarities to the control untreated silicon wafer which comprised a full oxide coating.

The plasma-reaction-formed $\alpha - SiH$ is proposed to comprise a more stable hydride ion than the H terminated silicon from HF treatment. Thus, the ion production efficiencies in ToF-SIMS analysis could be different making a comparison only qualitative and indicative of relative changes that occurred with timed air exposure. Since the $Si\ 2p$ electron of all samples was equivalent except for energy shifts due to the presence of ordinary or novel hydride, or oxide, qualitative analysis was possible as given in the XPS section. As shown in this section, the ToF-SIMS results were confirmed by XPS.

XPS

A survey spectrum was obtained over the region $E_b = 0\ eV$ to $1200\ eV$. The primary element peaks allowed for the determination of all of the elements present. The survey spectrum also detected shifts in the binding energies of the $Si\ 2p$ peak which also identified the presence or absence of SiO_2 .

The XPS survey scans of the noncoated cleaned commercial silicon wafer and a nickel foil coated with an α -*SiH* film and exposed to air for 20 min. before XPS analysis are shown in Figures 11 and 12, respectively. The major species identified in the XPS spectrum of the control sample were silicon, oxygen, and carbon; whereas, the α -*SiH* sample contained essentially silicon alone with negligible oxygen and carbon present.

The XPS spectra (96-108 eV) in the region of the *Si 2p* peak of the noncoated cleaned commercial silicon wafer and a nickel foil coated with an α -*SiH* film and exposed to air for 20 min. are shown in Figures 13 and 14, respectively. The XPS spectrum of the control silicon wafer shows a large SiO_2 content at 104 eV as given by Wagner et al. [39]. In contrast, the α -*SiH* sample had essentially no SiO_2 . In addition, spin-orbital coupling gives rise to a split *Si 2p* peak in pure silicon, but this peak changed to a single broad peak upon reaction to form the α -*SiH* film indicative of amorphous silicon.

The XPS spectrum (96-108 eV) in the region of the *Si 2p* peak of a nickel foil coated with an α -*SiH* film and exposed to air for 48 hours before the XPS analysis is shown in Figure 15. Essentially no SiO_2 was observed at 104 eV demonstrating that the sample was extraordinarily stable to air exposure. Perhaps trace *SiOH* is present in the region of 102 eV potentially due to less than 100% coverage of the surface with the α -*SiH* film; rather, some silicon deposition may have occurred. In contrast, the XPS spectrum (96-108 eV) in the region of the *Si 2p* peak of the *HF* cleaned silicon wafer exposed to air for 10 min. before XPS analysis was essentially fully covered by partial oxides SiO_x such as *SiOH*. The mixed silicon oxide peak in the region of 101.5-104 eV

shown in Figure 16 was essentially the same percentage of the Si 2p as that of the SiO₂ peak of the uncleaned wafer shown at 104 eV in Figure 13. In addition, the O 1s peak of the α -SiH film exposed to air for 48 hours shown in Figure 17 was negligible; whereas, that of the HF cleaned wafer exposed to air for 10 min. was intense as shown in Figure 18.

The 0-70 eV and the 0-85 eV binding energy region of high resolution XPS spectra of the commercial silicon wafer and a HF cleaned silicon wafer exposed to air for 10 min. before XPS analysis are shown in Figures 19 and 20, respectively. Only a large O 2s peak in the low binding energy region was observed in each case. The 0-70 eV binding energy region of a nickel foil coated with an α -SiH film and exposed to air for 20 min. before XPS analysis is shown in Figure 21. By comparison of the α -SiH sample to the controls, novel XPS peaks were identified at 11, 43, and 55 eV. These peaks do not correspond to any of the primary elements, silicon, carbon, or oxygen, shown in the survey scan in Figure 12, wherein the peaks of these elements are given by Wagner et al. [39]. Hydrogen is the only element which does not have primary element peaks; thus, it is the only candidate to produce the novel peaks and correspond to the H content of the SiH coatings. These peaks closely matched hydrides formed by the catalytic reaction of He⁺ with atomic hydrogen and subsequent reactions to form highly stable silicon hydride products α -SiH that were discussed previously [36].

These results indicate that the plasma reaction formed a highly stable novel hydrogenated coating; whereas, the control comprised an oxide coating or an unstable hydrogen terminated silicon surface which rapidly formed an oxide passivation layer. The hydrogen content of the α -SiH coating appears to be novel silicon hydrides with high binding energies which account for the exceptional air stability.

IV. CONCLUSIONS

Nickel substrates were coated by the reaction product of a low pressure microwave discharge plasma of SiH_4 (2.5%)/ He (96.6%)/ H_2 (0.9%). The ToF-SIMS identified the coatings as hydride by the large SiH^+ peak in the positive spectrum and the dominant H^- in the negative spectrum. XPS identified the H content of the SiH coatings as hydride corresponding to peaks at 11, 43, and 55 eV, respectively, in the absence of any other identifiable primary element peaks. The novel hydrides are proposed to form by the catalytic reaction of He^+ with atomic hydrogen with subsequent reactions to form highly stable silicon hydride products. The SiH coating was amorphous as indicated by the shape of the $\text{Si } 2p$ peak and was remarkably stable to air exposure. After a 48 hour exposure to air, essentially no oxygen was observed as evidence by the negligible $\text{O } 1s$ peak at 531 eV and absence of any SiO_x $\text{Si } 2p$ peak in the region of 102-104 eV. The highly stable amorphous silicon hydride coating may advance the production of integrated circuits and microdevices by resisting the oxygen passivation of the surface and possibly altering the dielectric constant and band gap to increase device performance.
